ABSTRACT

This article reports two patients with hepatocellular carcinoma (HCC) and type 2 diabetes mellitus (T2DM), who showed marked changes in hepatocellular glycogen content. Periodic acid-Schiff (PAS)-positive and diastase-PAS-negative (glycogen-storing) hepatocytes were detected in both background liver parenchyma and in HCC tissues. In HCC tissues, the number of glycogen-storing cells resembling hepatocytes was considerably reduced and unevenly distributed as compared with hepatocytes in background liver. To be known, changes in hepatocellular glycogen content in T2DM patients have not been previously described. It is hypothesized that the reduction in glycogen content in both patients was likely associated with the emergence of Warburg type of glycolysis.

Key words: Glycogen; hepatocellular carcinoma; hexokinase II; steatohepatitis; type 2 diabetes mellitus

INTRODUCTION

Most cases of hepatocellular carcinoma (HCC) occur in patients with chronic liver disease and advanced fibrosis. Well-known causes of chronic liver disease leading to HCC include chronic hepatitis B virus (HBV) and hepatitis C virus infection,[1] chronic alcohol abuse[1,2] and more recently, non-alcoholic fatty liver disease (NAFLD).[3] In addition, type 2 diabetes mellitus (T2DM) has been associated with HCC.[4] Patients with T2DM and NAFLD-related non-cirrhotic or cirrhotic livers may develop HCC, suggesting a role for T2DM in hepatocarcinogenesis.[2]

Glycogen loading of the liver was first documented as a component of Mauriac's syndrome in 1930, and...
enhanced glycogen deposits were observed with increasing frequency in patients with brittle diabetes.[5,6] Excessive storage of glycogen [glycogen-storing foci (GSF)] has been observed in pre-neoplastic foci of altered hepatocytes (FAH), and in highly differentiated subpopulations of benign and malignant hepatocellular lesions in animal models of hepatocarcinogenesis.[7,8] Glycogenotic cells (clear cell) have been observed in liver biopsies and explants from the patients harboring foci and nodules of altered hepatocytes.[10,11] Although clear cell HCCs have been described, their glycogen content was usually not determined.[12]

To our knowledge, there have been no comparative studies on changes in hepatocellular glycogen content of HCC and background livers in patients with T2DM. This study describes two patients with HCC and T2DM, who showed marked changes in hepatocellular glycogen content.

CASE REPORT

Case 1
A 72-year-old Japanese man with T2DM and alcoholic liver disease was diagnosed with HCC by computed tomography (CT) examination. Laboratory data showed aspartate transaminase (AST) 95 IU/L, alanine transaminase (ALT) 65 IU/L, alpha-fetoprotein (AFP) 8.2 ng/mL, protein-induced by vitamin K absence factor II (PIVKA-II) 26 mAU/mL, fasting blood sugar (FBS) 228 mg/dL, and hemoglobin A1c (HbA1c) 7.9%. CT arterial portography and CT hepatic arteriography revealed 2 minor nodules (3-4 mm) at S5, and a larger nodule (2.5 cm × 2.3 cm) at S8.

A specimen, obtained from needle biopsy of the S8 tumor, was fixed with Carnoy’s solution, and formalin for a routine histological diagnosis. Samples were stained with periodic acid-Schiff (PAS) and PAS after diastase pre-treatment (D-PAS). Hexokinase II (HK-II) was detected immunohistochemically using anti-HK II (C64G5) rabbit mAb (Cell Signaling Technology, Inc. Danvers, US). HK-II activity in positive control was also indicated [Figure 1a and b].

Histologic examination showed a well- to moderately-differentiated HCC [Figure 2a], with the background liver showing steatohepatitis with alcoholic pericellular fibrosis [Figure 2b]. Both PAS-positive [Figure 2c and d] and D-PAS-negative (glycogen-storing) hepatocytes [Figure 2e and f] were detected in the background liver and in HCC tissues. However, the PAS-positive hepatocytes were more abundant in the background liver than in the HCC tissues. No pronounced clear cells were detected. HK-II expression was weak in HCC [Figure 2g] and faint in background liver [Figure 2h]. Clinical and pathological data are summarized in Table 1.

Case 2
A 73-year-old Japanese man with T2DM and non-alcoholic steatohepatitis (NASH) was diagnosed with HCC by CT examination. At the age of 64, he was diagnosed with T2DM and NASH via needle biopsy of the liver. Laboratory examination showed AST 51 IU/L, ALT 22 IU/L, AFP 4.4 ng/mL, PIVKA-II 22 mAU/mL, FBS 140 mg/dL, and HbA1c 6.3%.

Partially, hepatectomized liver tissue was fixed as described in Case 1. Macroscopically, the HCC was revealed as simple nodular type (size, 1.8 cm × 1.5 cm; stage 1, T1N0M0; Child-Pugh grade A). Histological examination showed a well-differentiated HCC [Figure 3a], with the background liver presenting as type B cirrhosis [Figure 3b]. PAS-positive [Figure 3c and d] and D-PAS-negative [Figure 3e and f] hepatocytes were detected in both background liver and in HCC tissues, although the PAS-positive hepatocytes were more abundant in background liver than in the tumors. HK-II was weakly expressed in HCC [Figure 3g] and faintly expressed in background liver [Figure 3h]. No obvious clear cells were detected.

DISCUSSION

This study describes the two patients with T2DM, who developed HCC. Background liver in both patients showed steatohepatitis, suggesting that HCC may have been mainly due to steatohepatitis. The alcohol intake may have been a risk factor for HCC in Case 1,[18] whereas occult HBV infection with positivity for hepatitis B surface anti-body/hepatitis B core anti-body may have been a risk factor in Case 2.[13]

Glycogenotic hepatocytes are a common pre-neoplastic liver lesion in human at a high risk of HCC development.[11,14] FAH, including GSF, was detected in
84 of 111 (75.7%) patients with cirrhotic liver diseases, with a higher incidence in patients HCC than those without HCC.\(^{[11]}\) GSF were also detected in a significant number of human non-cirrhotic livers (88 of 236; 33.6%).\(^{[15]}\) A combination of enzymatic and molecular biological approaches has shown the striking similarities in metabolic changes in human and rat GSF, including the activation of the AKT/mammalian target of rapamycin (mTOR) and Ras/MAPK signaling cascades.\(^{[15]}\) Studies in more than 150 human explants showed the evidence for a characteristic sequence of cellular changes, from pre-neoplastic glycogenotic FAH via various intermediate stages [mixed cell foci (MCF)] to glycogen-poor malignant phenotypes, similar to that in animal models.\(^{[9,11]}\) These phenotypic cellular changes are due to a metabolic switch from gluconeogenesis toward the pentose phosphate pathway and the Warburg type of glycolysis.\(^{[9,11]}\) In human HBV-associated tumorigenesis, the mTOR signaling cascade has been shown to play a crucial role in driving the metabolic alterations toward increased aerobic glycolysis.\(^{[16]}\) When initial excess glycogen stores are reduced, the storage of polysaccharides is often largely replaced by the accumulation of neutral lipids.\(^{[17]}\) In both of our patients, PAS-positive/D-PAS-negative hepatocytes, which store glycogen albeit not the excessive amounts, were detected in background livers and HCC tissues. Neither pronounced clear cells nor MCF were detected. Fat deposits were rare in HCC tissues and background livers of both these patients. Changes in glycogen content frequently accompany a shift in the expression of isoenzymes during progression, e.g., from low-affinity (glucokinase/HK IV) to high affinity (HK-II) HK.\(^{[17,18]}\) HK-II being characteristic of Warburg type of glycolysis occurring in rapidly growing tumors, including HCC.\(^{[17,19]}\)

DM: diabetes mellitus; HBsAg: hepatitis B surface antigen; cAb: core anti-body; sAb: surface anti-body; HCV: hepatitis C virus; HCC: hepatocellular carcinoma; PAS: periodic acid-Schiff; HK-II: hexokinase II; NASH: non-alcoholic steatohepatitis
Guzman reported that the higher levels of HK-II in HCC were associated with more aggressive histological behavior; however, HK-II expression was not associated with DM.[20] HK-II was expressed in both the HCC tissues and background liver parenchyma of our patients, but its intensity was inversely related to PAS-positivity, being higher in cells with lower glycogen content. Histological examination showed that our HCC patients have less aggressive phenotypes. It is hypothesized that the reduction of glycogen content in HCC may, therefore, be associated with the appearance of Warburg type of glycolysis. Non-invasive monitoring of the glycogen content of the liver might serve as a basis for predicting the development of HCC. Unfortunately, such an approach is currently not available.

In summary, this study described the two patients with HCC and T2DM, both of whom experienced marked changes in glycogen content in HCC tissues and background liver parenchyma. These studies in larger numbers of patients are needed to clarify a possible relationship between the changes in hepatocellular glycogen content and the development of HCC in diabetic patients with steatohepatitis.
